Ltd., Tochigi, Japan

Abstract: Objectives: The aim of this study was to compare the effects of certain commercially available mouthwashes on cariogenic bacteria and biofilms, following the acquisition of inhibition potentials of caries. Materials and Methods: Mouthwashes containing I) chlorhexidine gluconate (CHG; 0.0005\% w/v), II) benzethonium chloride (BTC; 0.01\% w/v), III) an essential oil (Listerine), and IV) povidone-iodine (PVP-I; 0.035\% w/v) were tested on planktonic cariogenic bacteria, biofilms, and an ex vivo caries model. Bacterial aliquots were inoculated with each solution separately and vortexed for 10 seconds at room temperature. Bacterial viability was subsequently investigated by fluorescence microscopy (FM) after staining with a BacLight viability kit and the number of colony-forming units (CFUs) was counted. Similarly, mouthwash solutions were applied to artificial cariogenic biofilms, and bacterial viability of the biofilms was investigated as stated above. Inhibition potentials of two selected mouthwashes of carious lesions were investigated using biofilm-induced caries and a secondary caries model. In all steps, a phosphate-buffered saline (PBS) solution was included as a control. Results: Planktonic cariogenic bacteria and bacteria embedded in biofilms were killed in remarkably large numbers with Listerine and PVP-I treatment compared to PBS and other gargles. CFU counts also showed significant reduction after treatment with Listerine and PVP-I compared to other solutions (P<0.05). Listerine also displayed significant (P<0.05) inhibition effects in preventing the progression of demineralization. Conclusion: Bactericidal potencies of the mouthwashes varied significantly, suggesting that mouthwashes like Listerine can be useful for the prevention of caries and secondary caries.

Keywords: Cariogenic bacteria, cariogenic biofilms, inhibition of caries and secondary, mouthwashes, prevention of caries and secondary caries.

INTRODUCTION

The oral cavity is one of the most complex parts of the human body that consists of teeth, periodontal tissue, tongue and mucosa as well as secretory organelles and harbors a heterogeneous microbial community [1, 2]. The oral cavity remains highly prone to infectious diseases [2, 3]. Hundreds of bacterial species are involved in dental caries [4]; e.g., Streptococci species as well as lactobacillus species [5, 6]. Mutans streptococci generally include \textit{Streptococcus mutans} and \textit{Streptococcus sobrinus} in the biofilms and produce acids as a by-product of metabolism of fermentable carbohydrates [7, 8].

In recent years, there has been more concern about caries prevention and a call for preventive home care articles [9, 10]. Other than tooth brushing there are many mouthwashes available which appear to be more popular than tooth brushing in terms of convenience [10].

Antiseptic mouth rinse solutions are used in many clinical situations for different therapeutic and prophylactic purposes [11, 12]. Many of those are recommended for home-care practice [11]. It is difficult to decide which commercial product is suitable for a particular purpose because of the variations of the antimicrobial efficacy, cytotoxicity and kinetics of the solutions [13]. The main indications are either the improvement of dental health (plaque and gingivitis elimination in particular) or the prevention of infections caused by bacteria of the oral cavity in specific situations such as tooth extraction, intraoral surgical procedures or immune-suppression during cancer therapy or transplantation [14]. Occasionally, antimicrobial mouthwashes have been prescribed for controlling the levels of cariogenic bacteria and their plaque biofilms [15].

The objectives of this study were to compare the bactericidal effects of some commercially available mouthwashes on cariogenic bacteria and their effects on cariogenic biofilms. In addition, it was examined whether the application of mouthwash can inhibit the progression of demineralization by using an artificial caries and secondary caries model.
MATERIALS AND METHODS

The effects of different mouthwashes on cariogenic bacterial survival and caries-forming potential were evaluated in models employing: 1) cultured cariogenic bacterial cells; 2) cariogenic bacteria organized into biofilms; and 3) an ex vivo caries model.

EFFECTS ON CARIOGENIC BACTERIAL CELLS

Bacterial Isolates and Growth Media

Two laboratory strains of cariogenic bacteria, *Streptococcus mutans* MT8148 (*S. mutans*) and *Streptococcus sobrinus* 6715 (*S. sobrinus*), were used in this study. Bacteria cultures were established in brain heart infusion (BHI) broth (Becton Dickinson, Sparks, MD, USA®). After 16 hours, when bacteria were in an exponential growth phase, these cells were collected, washed 3 times with phosphate-buffered saline (PBS), and were suspended in PBS at 2.0 × 10^7 colony-forming units (CFU) per ml (correlating to an optical density at 500-nm wavelength [OD 500] of 2.0). Bacterial suspensions were stored at 4°C with continuous gentle stirring until use.

Solution Preparation

The solutions used in this study are listed in Table 1. Each commercial mouthwash was used at a dilution recommended by the respective manufacturer, and dilutions were made using Milli-Q water. PBS alone was included as a control.

Inoculation of Bacteria with Solutions

One-milliliter aliquots of the bacterial suspensions were centrifuged (800g 5 min 4°C), supernatants were discarded, and bacterial pellets were suspended in 1.0 ml of the test solutions by gentle vortexing. Immediately after 10-second incubation in test solutions, cell suspensions were centrifuged, the supernatants discarded, and cell pellets were suspended and held in 1.0 ml of chilled PBS to be analyzed for viability.

Bacterial Viability Test Using BacLight Kit

A LIVE/DEAD BacLight Bacterial Viability Kit (Molecular Probes, Invitrogen Detection Technologies, Carlsbad, CA, USA®) was used to evaluate bacterial cell killing by the test solutions. One-half (500 μl) of each bacterial sample was suspended in PBS and transferred into dark microtubes, and stained with 0.5 μl BacLight stain (a mixture of SYTO 9 and propidium iodide). In this staining system, viable bacterial cells exhibit green fluorescence, whereas nonviable bacterial cells exhibit red fluorescence. Selective dye uptake depends upon cell membrane integrity, allowing dead bacteria to be easily distinguished from viable bacteria. The excitation/emission wavelengths of the dyes were approximately 480/530 nm for SYTO 9 (green signals) and 520/580 nm for propidium iodide (red signals). Bacterial cells were evaluated using a fluorescence microscope (CKX41, Olympus, Tokyo, Japan®).

Colonies Forming Units of Bacteria

Each bacterial cell suspension (500 μl) was serially diluted to a 1000-fold final dilution, homogenized (UP50H, Dr. Hielscher, GmbH, Baden-Wuerttemberg, Germany®) before plating with a spiral plating instrument (Eddy Jet, IUL, Barcelona, Spain®). Treated and control *S. mutans* and *S. sobrinus* samples were plated in petri dishes containing Mitis Salivarius (MS) agar medium (Becton Dickinson, Sparks, MD, USA®). After a 48-hour incubation under anaerobic conditions at 37°C, the number of CFUs was counted by light microscopy.

Effects on Cariogenic Biofilms

We evaluated the effects of different mouthwashes on bacterial viability in cariogenic biofilms using previously detailed methods [16].

Enamel Slab Preparation

Bovine lower incisors from 20- to 24-month-old cattle were used to prepare square shaped dentino-enamel slabs in this study. Approximately 5×4×4-mm enamel slabs were
prepared from mid-labial tooth parts by excision using a low-speed diamond disc (IsoMet, BUEHLER, IL, USA) under running tap water as a coolant. The convex enamel surfaces were reduced down to 0.5 mm thickness using 800-grit silicone carbide paper under running tap water as a coolant. The convex enamel low-speed diamond disc (IsoMet, BUEHLER, IL, USA) prepared from mid-labial tooth parts by excision using a

Biofilm Formation

The S. mutans, S. sobrinus, and S. gordonii suspensions were used to form biofilms on the enamel slab surfaces that had been placed inside the water jacket-encircled chamber of an oral biofilm reactor (OBR) [17, 18]. Twenty enamel slabs were positioned on specimen holders in OBR chambers around a flat-bulb pH electrode using red utility wax (GC, Hanau, Germany) and a hybrid composite (Clearfil AP-X; Kuraray Medical, Tokyo, Japan) mounted in a milling machine (Cendres & Metaux SA CH-2501, Biel-Bienne, Switzerland), and cavities prepared on the surface of the enamel slabs using a 0.8-1.0 mm diameter regular-grit tapered burr (ISO #170, Shofu, Kyoto, Japan) mounted in a milling machine (Cendres & Metaux SA CH-2501, Biel-Bienne, Switzerland®), and cavities surfaces were finished with a straight burr (ISO #109, Shofu®) under water coolant. A light curing self-etching one component adhesive material (iBOND; Heraeus Kulzer, Hanau, Germany®) and a hybrid composite (Clearfil AP-X; Kuraray Medical, Tokyo, Japan®) were used to fill the cavities inside the OBR chambers for 12 hours.

Artificial biofilms were then grown on enamel sections to evaluate whether different mouthwashes can effectively inhibit caries formation (Fig. 2) [19, 20].

Mouthwash Potential to Inhibit Caries Formation

An artificial caries model was used for this experimental series to evaluate whether different mouthwashes can effectively inhibit caries formation (Fig. 2) [19, 20].

Enamel Slab Preparation, Cavity Formation, and Composite Restoration

Enamel slabs were prepared from bovine incisors as detailed above. After rinsing with ultrapure water, enamel sections were dried and coated with fingernail varnish (Fig. 2). Class-I cavities (3 mm long, 2 mm wide, 2 mm deep) were prepared on the surface of the enamel slabs using a 0.8-1.0 mm diameter regular-grit tapered burr (ISO #170, Shofu, Kyoto, Japan®) mounted in a milling machine (Cendres & Metaux SA CH-2501, Biel-Bienne, Switzerland®), and cavity surfaces were finished with a straight burr (ISO #109, Shofu®) under water coolant. A light curing selfetching one component adhesive material (iBOND; Heraeus Kulzer, Hanau, Germany®) and a hybrid composite (Clearfil AP-X; Kuraray Medical, Tokyo, Japan®) were used to fill the cavities.
ties. The lot numbers and chemical compositions of the materials with manufacturer instructions are listed in Table 2.

The cavities were not filled completely, and 0.8-mm-deep unfilled spaces remained as the site for biofilm accumulation (Fig. 2).

As detailed above, suspensions of exponentially growing S. mutans, S. sobrinus, and S. gordonii were washed three times in PBS, and suspended in chilled PBS with gentle stirring until use.

Growing Biofilms on Enamel Slabs Inside the OBR

Inside the OBR, artificial S. mutans, S. sobrinus, and S. gordonii biofilms were grown on each of the Class-1 cavities that were filled with resin composite material. After 24 hours in the OBR chamber, specimen with de novo biofilms were transferred to 24-well tissue culture plates (Corning Inc., New York, NY, USA) and were incubated at 37°C in HI medium containing 1% sucrose for a further 7 days, with media replenished every other day.

Evaluating Mouthwash Effects on Caries Development

During the 7-day incubation period in HI, specimens were rinsed with either Listerine, chlorhexidine gluconate (CHG), or PBS (n=4 replicated in each group) for 60 seconds once daily. Samples were mildly agitated in the test solutions using a water bath shaker operating at 10 Hz, for 20 seconds, three times, at 1-minute intervals.

Fluorescence Microscopic Evaluation of Caries

To detect and morphometrically measure the demineralized lesions in the caries model, at the end of the experiment, enamel samples were rinsed with PBS, and fixed in 4% paraformaldehyde and 1% glutaraldehyde in PBS for 1 hour. Samples were rinsed with PBS three times, followed by final rinsing in Milli-Q water, air-drying, and were then embedded in a self-curing epoxy resin (Epon 815, Nissin EM, Tokyo, Japan). Enamel specimens were subsequently ground with 800-grit silicon carbide paper and diamond paste to expose the longitudinal axis and provide a clear view of the cavity site. Secondary caries lesions at the enamel/composite interfaces were evaluated on an inverted fluorescence microscope, and imaged using a DP70 system with the aid of DP Manager Software (Olympus). Images were taken at 40 and 100 magnifications after setting a scale bar for each micrograph. Lesion areas were subsequently measured using Image_J V.1.34 software (NIH, Bethesda, MD) utilizing the scale bar on each image as a calibration reference. Only the regions of a lesion that remained adhered to resin were classified as secondary caries lesions (Fig. 2).

Statistical Analysis

All numerical data was analyzed using the Statistical Package for the Medical Sciences (SPSS Ver.11 for Windows, SPSS Inc., Chicago, IL, USA). The experiments were repeated three times under the same conditions to ensure reproducibility. For data from experiments comparing
mouthwash effectiveness against bacterial cell suspensions and biofilms, we used the non-parametric Kruskal-Wallis test initially for multiple comparisons, followed by the Mann-Whitney U-test to compare two sample sets (samples that showed no bacterial growth were excluded).

RESULTS

Bacterial Viability after Short Exposure to Different Mouthwashes

By fluorescence microscopy using the Live/Dead cell viability assay, live bacterial cells appear green and dead cells are red in the same microscopic image, following excitation with blue light (supplementary data). Clearly, more live bacterial cells are visible than dead cells in all experimental groups except for the cells treated with Listerine. Nearly 100% cells in our PBS controls were alive, and only slight killing was observed in bacteria treated with CHG. About 50% of bacteria died after treatment with povidone-iodine (PVP-I) or benzethonium chloride (BTC). Essentially all bacterial cells were killed after a short treatment with Listerine.

Colony Forming Units of Cariogenic Bacteria after Mouthwash Exposure

Colony counts (CFU/ml) of bacterial cells recovered from each sample are shown in Fig (3). Expectedly, the number of viable bacterial cells after incubation with the test solutions varied depending on the chemical components and their concentrations. Significantly more bacterial colonies were counted with cells that were treated with PBS and CHG compared to other solutions (P<0.05). Almost no colonies were observed when cells were treated with either Listerine or PVP-I. Both *S. mutans* and *S. sobrinus* bacteria cultures responded similarly to mouthwash exposure; in the case of BTC, however, *S. sobrinus* appeared to be more resistant to BTC antiseptic action.

Disinfection Effects after Penetration Inside Cariogenic Biofilms

The viability of bacterial cells recovered from each biofilm group is summarized in Fig. (4). Among “Top Layer” samples, there was no detectable colony growth following exposure to Listerine, PVP-I, or BTC, CHG showed more than $4 \times 10^6$ CFU/ml. BTC and PVP-I showed reduced
colony numbers compared to CHG. PBS controls, as expected, showed robust colony growth. Among “Middle Layer” biofilm samples, BTC and PVP-I resulted in significantly less colony growth compared to PBS controls. Listerine treatment resulted in no detectable colonies. Among “Bottom Layer” biofilm samples, CHG treatment resulted in more colonies than did BTC or PVP-I. Listerine treated biofilms generated only very few colonies and their numbers were significantly less than in all of the other groups.

Inhibition Potential of Mouthwashes Against Caries Progression

On fluorescence microscopic inspection, carious lesions were detected in enamel at the edge of resin restorations (Fig. 5a). These appeared as demineralized enamel that exhibited a whitish-green fluorescence (PBS group). In some cases, dislodgement of brittle enamel prisms after demineralization was also observed as dark voids (CHG group). The Listerine group had the smallest lesions among the three groups (Fig. 5a), which were significantly different (P<0.05) compared to the other two groups (Fig. 5b). The CHG group had smaller lesions compared to PBS group, but this difference did not reach statistical significance (Fig. 5b).

DISCUSSION

Mouthwashes experimented with in this study displayed heterogeneous potency in terms of bactericidal effects and inhibiting carious lesion formation. All four mouthwashes contain completely different chemical compositions. These compounds are mostly synthetically produced and have been used for many clinical purposes including, for example, dental plaque control, oral pathogen elimination, and to prevent and treat halitosis [21].

BTC, Listerine, and PVP-I were all effective in killing cariogenic bacteria after brief exposure in suspension. Listerine in particular showed the strongest disinfection effect on planktonic bacteria and on the bacteria that were protected inside biofilms by water insoluble glucans compared to other mouthwashes. This might be because Listerine contains multiple antibacterial reagents including essential oils and ethanol in high concentration, and is recommended to be used without dilution.

Mouthwashes including chlorhexidine digluconate and Listerine are being critically investigated for their disinfection effects against oral pathogens [22]. BTC, containing 0.01% (w/v) benzethonium chloride, is a commonly used antiseptic in Japan. The BTC product evaluated in the current work combines benzethonium chloride with tea tree and white thyme oils, both of which have been studied as antifungal agents [23, 24]. PVP-I not only destroys bacteria, but also effectively inhibits the release of pathogenic factors [25]. Listerine also has previously been demonstrated to exert significant microbicidal activity against oral microorganisms [26].

On the other hand, it has been reported that a 0.12% chlorhexidine mouth rinse was superior to Listerine in maintaining low plaque and gingivitis scores, in the absence of
mechanical plaque control [27]. However, in that study gargling with CHG for 10 seconds did not result in bactericidal activity when using 0.0005% CHG (i.e., a 100-fold dilution of standard 0.05% oral rinses). We actually did not expect that CHG would demonstrate bactericidal effects at such a low concentration when employed in the present experimental series. In Japan, the use of chlorhexidine is limited because it has caused allergic reactions and anaphylactic shock in some patients [28]. Because of this, only very low concentrations of CHG are permitted for homecare use, and all types of chlorhexidine-containing anti-bacterial agents are used with maximum caution [29]. CHG also contains monooammonium glycyrrhizinate, which is often used as a sweetening and flavoring agent, and also found to be effective in controlling lung inflammation in mice [30]. Perhaps, low CHG concentrations permit more frequent use for long-term prophylactic therapy with the additional benefit of controlling inflammation.

Of the different bactericidal mouthwashes that we evaluated for killing bacteria in suspension and in biofilms, we demonstrated that Listerine is the most potent and CHG is the weakest oral antiseptic. Therefore, we selected these two mouthwashes for further evaluation in caries inhibition assays. Data from these studies clearly showed that Listerine effectively inhibited the progression of caries and secondary caries development in our cavity model. Expectedly, CHG at the concentration of 0.0005% did not show a detectable bacterial inhibitory activity in this study.

The specimens with the undisturbed biofilms were inoculated for an additional 7 days to observe the ability of the two mouthwashes to inhibit the progression of carious lesions or enamel demineralization. In this study, a water bath shaker was used with a moderate stroke of 10 Hz for 20 seconds three times at 1-minute intervals to simulate the gargeting condition created by an adult.

Mouthwashes containing strong chemical reagents, such as Listerine, are not advisable for long-term continuous use. They not only dry up the mucous membranes and potentially damage soft tissues, but also may cause a severe imbalance in the oral microbial flora. Excessive use of low-pH mouthwashes over long periods of time is also of concern. The pH at which tooth demineralization begins is known as the critical pH, and is in the vicinity of pH 5.0 to 5.5. Demineralization is most rapid following acute exposure to pH 4.0, as is often observed in mature dental plaques after a sugar exposure [8, 31]. It was also reported that low pH mouthwashes and soft drinks have a variable potential to cause enamel erosion [32, 33]. Therefore, it is important to control the pH in the oral environment [34]. However, the critical pH level below which damage to the enamel or tooth demineralization is observed, is known to be 5.5 [6]. One unfortunate fact is that the pH-levels of currently available Listerine and PVP-I are both lower than the critical pH (Table 1). Periodic use, according to immediate need and under appropriate guidance of a specialized dental professional is important to obtain maximum benefit while avoiding potential chemical toxicity and subsequent oral tissue damage. One of the reasons for selecting a short exposure time (10 second vortex) of our bacterial suspensions and biofilms to the mouthwashes in this study was to provide evidence that short exposure to these antibacterial agents can be remarkably effective [34]. Short exposure times also minimize chemical biohazard concerns associated with oral antiseptic use.

CONCLUSION

Bactericidal potency varies significantly according to the specific chemical components and their concentrations of different mouthwashes. We suggest that mouthwashes such as Listerine can be useful for prevention of caries and secondary caries if used within appropriate guidelines. Further long-term studies including additional antibacterial mouthwashes or prophylactic mouthrinses, are recommended.
