Abstract: Our case-control studies were the first to report an association between the use of mobile or cordless phones and brain tumors; glioma and acoustic neuroma. Criticism of these results has been based partly on results from the Interphone studies conducted under the auspice of the International Agency for Research on Cancer (IARC). Here, we compare study design and epidemiological methods used in our studies and the Interphone studies. We conclude that while our results appear sound and reliable, several of the Interphone findings display differential misclassification of exposure due to observational and recall bias, for example, following low participation rates in both cases and controls and bedside computer guided interviews of cases rather than blinded interviews of cases and controls. However, as we have presented elsewhere, there seems to be a consistent pattern of an association between mobile phone use and ipsilateral glioma and acoustic neuroma using ≥ 10 years latency period.

Keywords: Acoustic neuroma, cellular phones, cordless phones, case-control studies, methods, Interphone, epidemiology, glioma, microwaves.

INTRODUCTION

An association between use of wireless phones and brain tumors has been increasingly discussed during the last decade. Such devices were introduced on the market in the early 1980’s but it was not until the late 1990’s that the penetration in the society increased dramatically. A number of case-control studies have been published, and there seems in a meta-analysis of these studies to be a consistent pattern of an association between mobile phone use and ipsilateral glioma and acoustic neuroma using ≥ 10 years latency period [1,2]. Thus, for glioma latency period of ≥10-years gave odds ratio (OR) = 1.2, 95% confidence interval (CI) = 0.8-1.9 and for ipsilateral use (same side as tumour) OR = 2.0, 95% CI = 1.2-3.4. Contralateral use did not increase the risk significantly, OR = 1.1, 95% CI = 0.6-2.0. Regarding acoustic neuroma OR = 1.3, 95% CI = 0.6-2.8 was calculated using ≥10-years latency period increasing to OR = 2.4, 95% CI = 1.1-5.3 for ipsilateral use, but for contralateral use no statistically significant association was found; OR = 1.2, 95% CI = 0.7-2.2. No clear association with meningioma was found [2].

Twelve of the published case-control investigations are a part of the ‘Interphone studies’. These were performed in 13 countries and used a common study protocol laid down by the International Agency for Research on Cancer (IARC) and sponsored by industry [3]. According to the contract for these Interphone studies, the funding industry has full access to the publication of results one week before they are publicly available. Some results of these studies have been published in individual countries, see below, but we are still awaiting the final results that seem, now to have been delayed for more than one year [4].

Our Swedish studies were among the first to indicate an association between use of cordless phones and brain tumors [1,2,5-9]. At the moment there are partly conflicting results between our studies and the published Interphone studies, although long-term effects do appear similar. It would seem pertinent therefore to compare the epidemiological methods used in our studies with those used in the Interphone studies in order to better understand the apparent differences in the results. The studies are discussed below, after a discussion of the only cohort study that exists in this area.

MATERIALS AND DISCUSSION

Cohort Study

Two publications resulted from a Danish cohort study [10,11]. The cohort consisted of people that at some time during the thirteen year period between 1982-1995 were registered for the use of mobile phone. According to the first publication following the study in 2001 follow-up continued until 1996 [10]. In that publication results were given for use of analogue (NMT) and digital (GSM) phones, these separate results were not given, however, in the updated publication in 2006 [11].

Results were also given initially for the duration of use of GSM phones. The results recorded 9 persons with brain tumors that had used GSM ≥ 3 years and in the same group a somewhat increased standardized incidence ratio (SIR) = 1.2, 95% confidence interval (CI) = 0.6-2.3 was found for brain and nervous system tumors. In the updated publication
no data were given for duration of use in years. It is to be noted that such data were not reported for NMT phones even in the initial publication [10].

In the latest publication the cohort was followed for seven more years, against the Danish Cancer Registry until 2002. However, the length of time during which mobile phone had been used was not up-dated. The only information that was given was the most general, that is whether or not the cohort member was a user at one point in time; one phone call per week for six months was the initial inclusion criteria. In the calculation of latency, the first year of registration was used, which was usually not equivalent to the total number of years of cellular phone use.

We know that during the first years of the 1980s almost all use of mobile phones was in cars with external antenna. These subjects were thus unexposed to microwaves. No information about that is given. Subjects appear to have been included as exposed although they were not.

More than 200 000 (32%) company subscribers were excluded. In fact, these are the heaviest users and billed 4.5 times higher than laymen in Sweden for example. They started use earlier than others but were included in the “non-user” group of the Danish population; the reference population.

In the study SIR was calculated to 1.21, 95% CI = 0.91-1.58 for temporal glioma, that is the most exposed area of the brain [11]. This finding was based on 54 persons. This should have been divided into phone type and first use i.e. latency period. There was no information regarding the ear used during phone calls and its correlation with tumor site. In our studies we found most consistent increased risk in the category of > 10 years use and the development of ipsilateral tumors [7,8].

Another methodological problem is that expected numbers were based on the general population. However, a large part of the population does use mobile phones and/or cordless phones, and this percent was not assessed at all for the study. This method gives an underestimate of the risk. In the group with first use ≥ 10 years significantly decreased SIR of 0.66, 95% CI = 0.44-0.95 was found for brain and nervous system tumors. This is an indication of methodological problems in the study.

Of the subscribers 85% were men and 15% were women, this appears to be a very skewed sex distribution. In fact there seems to be a ‘healthy worker’ effect in the study since SIR was significantly decreased to 0.93, 95% CI = 0.92-0.95 for all cancers. Certainly early mobile phone users are not familiar with the Swedish medical system for patients with these tumor types, we have chosen to discuss these two studies in more detail in the following analysis. We discuss in some detail the methods and results of these studies on glioma or meningioma [19,22]. These studies were part of a medical dissertation [32].

Case-Control Studies

From the Interphone study group eight publications give results for glioma [19-26] and seven for acoustic neuroma [24, 25, 27-31]. There are several methodological concerns that need to be addressed in these Interphone studies. Our own studies in this area are the largest outside the Interphone group and our methods and results must be compared with the Interphone studies, especially as we were the first to find a consistent pattern of an association between use of mobile phones and brain tumours. Furthermore, in contrast to our studies, the use of cordless phones was not assessed in the Interphone studies, or such details were not presented [19,22].

The Swedish Interphone Studies

The Swedish part of the Interphone studies may serve as a model of how these studies were performed using the same core protocol as other Interphone studies. Also, since we are familiar with the Swedish medical system for patients with these tumor types, we have chosen to discuss these two studies in more detail in the following analysis. We discuss in some detail the methods and results of these studies on glioma or meningioma [19], and acoustic neuroma [27]. These studies were part of a medical dissertation [32].

Regarding glioma the Swedish Interphone study [19] reported 23 ORs in Table 2 in the article and 22 of these were ≤ 1.0 and one OR = 1.0. For meningioma all 23 ORs were < 1.0, six even significantly so. These results indicate a systematic bias in the study unless use of mobile phones prevents glioma and meningioma, which is biologically unlikely. It should be noted that several of the overall ORs also in other Interphone studies were < 1.0, some even significantly so. As an example, in the Danish Interphone study on
Use of Mobile Phones and their Association with Brain Tumors

Open Environmental Sciences, 2008, Volume 2  

problems with concentration and may have problems with other cognitive shortcomings. According to our experience a better option would have been to start with a mailed questionnaire, that can be answered by the patient during a period of more well-being, if necessary this can be complemented by a telephone interview. This procedure has the additional advantage that it can be accomplished without disclosure during the data collection, whether a person is a case or a control.

The diagnosis of tumor type as well as grading is based on histopathology. X-ray investigation or MR alone is insufficient. Of the 371 cases with glioma in the Swedish Interphone study [19] histopathology examination of the tumor was available for 328 (88%) and for 225 (82%) of meningioma. Thus, it is possible that cases without histology confirmation of the diagnosis may have had another type of brain tumor or even brain metastases. Such misclassifications inevitably bias the result towards unity. It is remarkable that 345 glioma cases were stratified according to grade I-IV, although histopathology was available only for 328 cases. In our studies on brain tumors we have histopathology verification of all of the diagnoses.

For analysis of laterality (ie. the risk of brain tumors on the same side or the opposite side the mobile phone was held during phone calls) an interesting approach was applied in the Swedish Interphone studies. The researchers split the cases into two subsets: those with left and those with right side tumors. Controls were randomly allocated to one of these subsets at a 1:1 ratio. Odds ratios calculated within these subsets were then pooled to give an overall estimate. This method is in principle correct for studies with unmatched controls. However, exposure categorization was questionable for ipsilateral but completely faulty for contralateral use of a mobile phone. Subjects were considered exposed if they used the phone on the same or on both sides of the head. On the other hand, if they used the phone on the contralateral side or did not regularly use a mobile phone they were considered unexposed.

Hence the reference category contained subjects using a mobile phone regularly but reported use on the other side of the head, as the tumor was located. Although exposure to microwaves from mobile phone use is substantially lower on the contralateral side, this discrepancy is less pronounced for regions of the brain (the ventricular and subventricular space) where glioma may originate. Therefore, the chosen procedure introduced exposure misclassification which could have biased the results. For contralateral exposure the opposite exposure classification was used. Patients with tumors on the same side as their exposure were considered part of the reference group. This is an obvious methodological flaw because risk for contralateral exposure would have to be decreased by including ipsilateral exposed cases in the reference group.

It should be pointed out that another weakness in the glioma and meningioma study was that for 33 glioma and 8 meningioma cases information on exposure was obtained from relatives, whereas no relatives of the controls were interviewed [19]. According to our experience relatives have
difficulties in giving information on the use of cellular telephones, especially about the side of the head the phone most frequently used during phone calls.

There are some discrepancies concerning number of cases identified and data in the Swedish Cancer Registry. We used the same criteria for case recruitment from the Swedish Cancer Registry. For example the Cancer Registry contained 469 cases with intracranial glioma cases compared with the 499 in the Interphone study, 337 meningioma cases versus 320, and 122 acoustic neuroma cases compared with 160 in the Interphone study [19,27]. The study included cases from neurosurgery, oncology and neurology clinics as well as regional cancer registries in the study areas, and there seems thus to be inconsistency with the numbers in the Cancer Registry.

Among the controls in the glioma and meningioma study 282 (29%) refused to participate [19]. Among some of these non-responders a short interview was made and only 34% reported regular use of a cellular telephone compared with 59% of the responders. If this discrepancy extends to the total group of non-responders the ‘true’ percentage of mobile phone users in controls would be approximately 52%. Hence this figure would be lower than in glioma (58% exposed) and acoustic neuroma cases (60%). Only for meningioma with 43% exposed cases a lower percentage was reported, however, considering the sex ratio (women:men) for meningioma of about 2:1 a lower percentage of mobile phone users has to be expected due to the lower rate of users among women. It should be noted, however, that a similar procedure in another Interphone study yielded similar results regarding mobile phone use among responders and non-responders [26].

It was discussed in the medical dissertation [32] that: ‘Our Swedish study, that includes a large number of long-term mobile phone users, does not support the few previously reported positive findings, and does not indicate any risk increases neither for short-term or long-term exposures.’ Considering the methodological shortcomings and that in contrast to the cited assertion of ‘a large number of long-term users’ the study subjects included only 25 glioma and 12 meningioma cases with long-term use, its conclusion seems to be going a long way beyond what can be scientifically defended.

It should be pointed out that one of the authors (Ahlbom) had stated, before the study started, that an asserted association between cellular telephones and brain tumors is ‘biologically bizarre’ [35]. This statement might occlude him from objectivity in his own investigation. The REFLEX-study indicates that there are biological mechanisms that could link exposure to the development of diseases such as brain tumors [36].

**General Comments**

In Table 1 methodological aspects on the Hardell et al. and Interphone studies are presented. Several issues may be discussed.

Both sets of studies had the case-control design, included both women and men and were performed during a similar time period, except for the first Hardell et al. study that included cases and controls for the time period 1994-1996 [5,6]. Our studies included cases and controls aged 20-80 years, whereas the Interphone studies included various age groups, mostly the age groups 20-69 years or 30-69 years, c.f. [1].

In the Interphone studies deceased cases were included with interviews of relatives, but only living controls. This might have introduced recall bias since it is probably difficult for relatives to know mobile phone habits, ear used during phone calls, type of phone etc. In our studies only living cases and controls were included. It is unlikely that excluding deceased cases would have biased the results unless use of wireless phones gives decreased OR for deceased cases; to balance an increased OR among living cases.

One large difference between our studies and the Interphone studies was assessment of exposure, as discussed above. We used postal questionnaires that were blinded as to case or control status during assessment of exposure and data coding. The questionnaire was sent home to the cases, in general about two months after the diagnosis. This gave a more relaxed situation for the cases compared with the Interphone studies where mostly bedside interviews were performed during the patients’ stay at the hospital, some even newly operated upon.

Obviously in the Interphone studies the case and control status was known during the interviews and processing of data in the computer. Observational bias might have been introduced in these studies since the interviewer knew if it was a case or control that was being interviewed. In contrast, assessment of exposure and all further data processing until statistical analysis was blinded as to being a case or a control in our studies. Assessment of exposure was similar for cases and controls.

It might have been a stressful situation for the cases with bedside interviews in the Interphone studies creating recall bias. In one of the Interphone studies Mini-Mental State Examination was completed by 80% of the cases and 90% of the controls [20]. It was concluded that patients scored significantly lower than controls due to recalling words (aphasia), problems with writing and drawing due to paralysis. Certainly these cognitive defects would not be expected to the same extent for patients with acoustic neuroma and clearly in the Swedish Interphone studies the results for acoustic neuroma [27] seem to be more sound and reliable than for glioma and meningioma [19].

We included use of mobile or cordless phone ‘any time’ in the exposed group and made dose-response calculations based on number of hours of cumulative use. The unexposed group included also subjects with use of wireless phones with ≤1 year latency period.

On the contrary, mobile phone use in the Interphone studies was defined as ‘regular use’ on average once per week during at least 6 months, less than that was regarded as unexposed including also all use within < 1 year before diagnosis. This definition of ‘regular use’ seems to have been arbitrarily chosen and might have created both observational
and recall bias in the interpretation of such a vague definition.

Use of cordless phones was not assessed or not clearly presented in the Interphone studies, e.g. [19, 22]. We found a consistent pattern of an association between cordless phones and glioma and acoustic neuroma [7,8]. It has been shown that the GSM phones have a median power in the same order of magnitude as cordless phones [37]. Moreover, cordless phones are usually used for longer calls than mobile phones [7,8]. Including subjects using cordless phones in the “unexposed” group in studies on this issue, as for example in the Interphone investigations, would thus underestimate the risk and bias OR against unity.

In Table 2 we present response rates for cases and controls in the various studies. The case participation was good in our studies, 88% for cases with benign brain tumours, 90% for malignant brain tumour cases and 89% for the controls. On the contrary case participation varied from 37% to 93% and control participation from 42% to 75% in the Interphone studies. Obviously low participation rates for cases and controls might give selection bias and influence the results in the Interphone studies.

Methodological issues in the Interphone studies have been discussed elsewhere [38,39]. It was concluded that the actual use of mobile phones was underestimated in light users and overestimated in heavy users. Random recall bias could lead to large underestimation in the risk of brain tumours associated with mobile phone use. It was further suggested that selection bias in the Interphone study resulted in under selection of unexposed controls with decreasing risk at low to moderate exposure levels.

The Interphone studies have been discussed in letters to the Editor regarding e.g. the German study on glioma and meningioma [22,40], the UK study on glioma [21,41,42], the study on acoustic neuroma in five countries [29,43-45], the Swedish study on glioma and meningioma [19,46], and the Danish study on acoustic neuroma [28,47,48]. Thereby similar critique as in this presentation has been made.

CONCLUSION

Our study group was the first to report a consistent pattern of an association between wireless phones and glioma and acoustic neuroma, whereas this was not found for meningioma. Meta-analysis of all published studies in this area using a reasonable latency period of at least 10 years confirmed this finding for use of mobile phones and ipsilateral
glioma and acoustic neuroma, but no significant association was found for meningioma [1,2]. Our studies have been attacked by unfounded critique as we have explored in detail elsewhere [37], but also in the publications presenting our case-control studies. Based on a comparison between our studies and the Interphone studies our results seem to be sound and reliable whereas several of the Interphone findings are prone to differential misclassification of exposure due to e.g. observational and recall bias.
