A Review of Hepatitis B Management in Pre- and Post-Liver Transplant Recipients

Sandeep Mukherjee*

Section of Gastroenterology and Hepatology, University of Nebraska Medical Center, Omaha, Nebraska, USA

Abstract: Liver transplantation was approved for treatment of decompensated cirrhosis in the United States in 1983. Hepatitis B and hepatitis C viruses are the leading causes of liver transplantation for viral hepatitis and hepatitis B is also an important cause of liver transplantation for called acute liver failure) due to either acute hepatitis B or an acute exacerbation of chronic hepatitis B. However, until the introduction of hepatitis B immunoglobulin and nucleoside/nucleotide analogues nearly twenty years ago, liver transplantation for hepatitis B was characterized by universal recurrence with a dismal prognosis. The widespread use of oral anti-virals in the US has led to a decreased incidence of decompensated liver disease and patients waitlisted for liver transplantation. Among patients listed for hepatocellular carcinoma, the decrease in waitlist registration was also least dramatic among patients with HBV, possibly related to the use of oral antivirals. At present, liver transplantation for hepatitis B, regardless of whether for decompensated cirrhosis, hepatocellular carcinoma satisfying Milan criteria or acute liver failure has excellent outcomes with results comparable if not better to other liver transplant recipients. This article will review the management of patients with decompensated cirrhosis from HBV prior to liver transplantation, the use of hepatitis B positive donors and the prevention and management of hepatitis B after liver transplantation.

Keywords: Hepatitis B, nucleos(t)ide, decompensated cirrhosis, liver transplantation, prophylaxis, hepatitis B immune globulins.

INTRODUCTION

Approximately two billion of the world’s population are infected with chronic hepatitis B (HBV) of whom 350 million have ongoing infection [1]. Although HBV is not endemic in the United States, some features on the epidemiology of this disease merit further discussion [2]. For example, the trend for listing patients for HBV-related liver disease has been declining in the United States since it peaked in 2000 with nearly 30% reduction in subsequent years according to registry data from the United Network for Organ Sharing (UNOS). The largest decrease in patients on the waiting list for liver transplantation (LT) occurred in patients with decompensated cirrhosis whereas the number of patients with hepatocellular carcinoma (HCC) increased. One possible explanation for these trends is the widespread use of antivirals for HBV, particularly lamivudine which was introduced in the late 1990’s. This was supported by a recent retrospective studying the impact of anti-viral therapies on waitlist registration for patients with viral hepatitis [3]. The investigators reported that of 113,927 waitlist patients, 4,793 (4.2%) had HBV. Furthermore, the incidence of waitlist registration for decompensated cirrhosis and acute liver failure (ALF) decreased whereas that for HCC increased. Interestingly, the decrease in registration for decompensated cirrhosis was most pronounced and the increase in HCC least dramatic among registrants with HBV. These findings were indicative that population-wide application of oral antiviral therapy for HBV contributed to the decreased incidence of decompensated liver disease.

Indications for liver transplantation for HBV include decompensated cirrhosis, HCC and ALF. ALF may sometimes be difficult to distinguish from severe exacerbations of chronic HBV which occur spontaneously during the immune reactive phase of chronic HBV or may be reactivated by immunosuppressive medications or chemotherapathy [4-6]. A large number of cases of reactivation are subclinical and resolve spontaneously or result in chronic hepatitis which may go undetected until patients present with decompensated cirrhosis. The importance of reactivation rests not only on its potential life-threatening complications but the ease of its prevention with oral antiviral therapy [7].

GUIDELINES FOR THE MANAGEMENT OF HEPATITIS B

In 2008, the European Association for the Study of Liver Diseases (EASL) published clinical practice guidelines and revised recommendations for the management of chronic HBV [8]. The guidelines divided treatment into short-and long-term strategies. Finite treatment with interferon-based therapy is recommended for those with the highest chance of achieving a sustained response when therapy is completed. Finite treatment with nucleosides/nucleotides is also considered for HBV e antigen (HbeAg) positive patients who achieve seroconversion during therapy. Long-term therapy with nucleosides/nucleotides is only recommended for patients unable to achieve a sustained viral response when therapy is discontinued. The EASL guidelines also emphasize that when choosing an oral therapy, preference should be given to anti-virals which are potent and have a
low incidence of developing drug-resistance in naïve patients, such as entecavir and tenofovir [9]. The EASL guidelines concluded with the following 12 unresolved issues that required further study:

1. Improvement in the knowledge of the natural history of immunotolerant patients with long-term follow-up of cohorts; experimental studies to provide more definite prognostic information and biomarkers to determine prognosis and indications for treatment.

2. Development and assessment of new therapeutic approaches, particularly immunomodulatory therapies to enhance loss of HBeAg and HBsAg and subsequent seroconversion.

3. Assessing the role of indirect markers (serum and biophysical) to assess the severity of liver disease and for the follow-up of treated and untreated patients.

4. Assessing the role of HBV genotype to determine prognosis and response to therapy and the risk of resistance.

5. Assessing the efficacy of different durations (24 weeks to 2 years) and lower doses of pegylated interferon alpha.

6. Assessing long-term efficacy and safety and resistance profiles to new analogues (entecavir, telbivudine and tenofovir).

7. Better definition of monitoring algorithms: timing of HBV DNA measurement with the new generation of nucleosides with a high genetic barrier to resistance; role of genotypic resistance assays in adapting therapy.

8. Assessing the role of combination therapy with 2 nucleosides to reduce resistance.

9. Assessing the efficacy of the combination of pegylated interferon alpha with potent nucleosides (entecavir or tenofovir) to increase HBe and HBs seroconversion rates.

10. Development of new drugs to manage multiresistant HBV resistant to both lineages of current NUC’s.

11. Assessing long-term impact of therapy on the prevention of cirrhosis and its complications and HCC.

12. Developing effective and optimum treatment for HDV infection.

The National Institutes of Health (NIH) convened a conference in October 2008 to reach consensus on the management of chronic HBV [10]. A central aim of the task force was to evaluate available randomized controlled trials on anti-viral therapy for chronic HBV between 1990 and 2008. A key but somewhat controversial conclusion of the review was that available data did not provide sufficient information required for decision-making in the long-term treatment of chronic HBV. For example, the panel concluded that randomized controlled trials looked at short term results and surrogate markers such as normalization of liver function tests, suppression of HBV deoxyribonucleic acid (DNA) and improvement in liver histology but few studies assessed the impact of treatment on risk of hepatic decompensation, HCC or death. However, it is important to reiterate that the NIH is not suggesting that clinicians should abstain from treating HBV but rather that data from available randomized studies was not available to confirm the effects of HBV therapy on clinical outcomes.

In December 2008, an expert panel of hepatologists published a treatment algorithm for the management of chronic HBV [11]. The Keeffe panel recommended entecavir, tenofovir and pegylated interferon alfa-2a as the preferred first line treatment for chronic HBV. The panel stated that all three therapies demonstrated superior efficacy and safety over comparators in pivotal clinical trials in HBeAg-positive and negative patients. The panel did not recommend lamivudine despite its excellent safety profile due its high rate of drug resistance and data clearly demonstrating superiority of entecavir to lamivudine. They recommended that tenofovir should substitute for adefovir as a first line agent but stated that the role of telbivudine was unclear.

**MANAGEMENT OF DECOMPENSATED CIRRHOSIS FROM CHRONIC HEPATITIS B**

Until the development of hepatitis B immunoglobulin (HBIG) and oral anti-virals, the presence of active HBV replication was considered a contraindication to LT as severe recurrent disease was universal. The introduction of anti-virals in decompensated cirrhosis had several advantages including deferring LT in a proportion of patients whose clinical condition improved and reducing or clearing HBV DNA prior to LT and thus decreasing the development of recurrent disease after LT [12]. As interferon-based treatment is contraindicated in decompensated cirrhosis, only nucleoside/nucleotide analogues have been evaluated in these patients.

**Lamivudine**

Several studies have evaluated the impact of lamivudine, a nucleoside analogue which inhibits viral polymerase, on HBV replication in decompensated liver disease. Although lamivudine is well-tolerated even in patients with advanced liver disease and can achieve rapid viral suppression the incidence of drug resistance is approximately 20% per year [13]. In a multicenter study of 77 patients treated with lamivudine 100mg per day, Perrillo et al. reported that lamivudine was partly effective in preventing recurrent HBV infection when administered before and after LT [14]. Patients in this study were treated while on the waiting list and continued after LT - although all patients were HBV surface antigen (HbsAg) positive, 61% were eAg-positive with detectable HBV DNA. 47 patients underwent LT and 30 did not. In the transplanted group, 59% of patients were HbsAg-positive at treatment week 156 and all 9 reinjected patients were HBV DNA positive before treatment. In the non transplant group, HbeAg was initially detectable in 74% of patients but decreased to 18% after 108 weeks of treatment. HBV DNA polymerase mutations were noted in 21% and 20% of transplanted and non-transplanted patients, respectively. Although this prospective study was limited by an absence of a control arm, the investigators concluded that lamivudine-treated patients appeared to have improved survival and transplanted patients had a decreased incidence of recurrent HBV compared to historical controls.
A prospective, multicenter trial by Fontana et al. also evaluated the impact of lamivudine on 154 patients listed for LT [15]. 21% of patients died during the study with the majority of deaths (78%) occurring in the first 6 months of therapy. In multivariate analysis, the severity of liver disease prior to initiation of lamivudine was a better predictor of early mortality than the virological response to lamivudine and the investigators recommended that regardless of the response to lamivudine, patients with decompensated cirrhosis should be transplanted promptly.

Although most of the studies evaluating lamivudine therapy with post-LT outcomes for HBV consistently recommend antiviral therapy should be started as soon as possible due to significant clinical improvement from antivirals, the high rate of drug-resistance with lamivudine remains problematic, particularly as the incidence of resistance increases the longer treatment is continued. This in turn has led to cases where LT has been performed in lamivudine-resistant cases with controversial outcomes and reports of recurrence occurring in a graft despite the use of lamivudine with HBIG post-LT [16, 17]. Lamivudine is well-tolerated with few side effects and has clearly played an important role in the management of decompensated cirrhosis prior to LT—however, the high incidence of viral resistance not observed with the new generation of nucleoside/nucleotide antivirals will likely make it obsolete in the near future.

**Adefovir**

Adefovir dipivoxil is a nucleotide analogue of adenosine monophosphate which inhibits both wild type and lamivudine-resistant HBV. Due to the high incidence of resistance reported with lamivudine, the introduction of adefovir was both timely and life-saving for many patients. A landmark study by Schiff et al. treated 128 decompensated patients with lamivudine-resistance with adefovir 10 mg per day for a median of 18 weeks [18]. 81% achieved undetectable HBV DNA which was associated with normalization of serum alanine aminotransferase (ALT) in 76% of patients who had elevated baseline ALT. This was associated with an improvement in clinical status and Childs Pugh Score (CPS) in 90% of patients and a 1 year survival of 84% which compared favorably with historical controls.

An important aspect of this study was the long-term follow-up results which were reported in wait-listed (n=226) and post-LT (n=241) patients with lamivudine-resistance who were treated for medians of 39 and 99 weeks, respectively [19]. After 96 weeks, HBV DNA levels were undetectable in 65% of wait-listed and post-LT patients. 91% of patients classified as CPS B or C at baseline had an improvement of at least one point in their score at 48 weeks. 32 (14%) deaths were reported in the wait-listed group or within 30 days of their last dose of study drug. However, Kaplan-Meier estimates of survival for wait-listed patients were 86% at week 45 and 78% by week 96. Furthermore, out of 100 patients surveyed, 57 did not undergo LT of whom 21 were removed from the list due to marked clinical improvement. The Kaplan-Meier estimate of post-LT survival in patients treated with adefovir was 87% at three years compared to 44% at the same interval if antivirals were not prescribed. An interesting observation of this study was that among wait-listed patients who underwent LT, prevention against graft reinfection was similar between patients who received and did not receive HBIG over a 35 week period. Surprisingly, HbsAg was detected less frequently in patients who did not receive HBIG—it was present in 6% who received and 0% who did not received HBIG, respectively.

Nephrotoxicity remains an important although uncommon side effect of adefovir yet it was a cause of treatment discontinuation in 4% of patients, usually in those with underlying hepatorenal syndrome. Adefovir resistance was present in only 2% of patients after a follow-up of 144 weeks with the only resistance mutation noted in domain D of the polymerase/reverse transcriptase gene. However, it appears that the addition of adefovir to lamivudine rather than drug substitution would be the preferred intervention for the management of lamivudine-resistant HBV although where possible, sequence analysis of the polymerase/reverse transcriptase gene should be performed to better guide therapy rather than using rising viral loads or aminotransferases as surrogate markers of drug resistance [20, 21].

**Newer Nucleoside/Nucleotide Antivirals**

Entecavir, tenofovir and telbivudine are some of the latest antivirals being used in patients with chronic HBV although experience is limited in patients with decompensated cirrhosis. A variety of studies are being conducted to assess their safety and efficacy in this group of patients. Preliminary reports are encouraging with case reports and studies strongly supporting a role for introduction of these newer agents in patients with lamivudine and/or adefovir-resistance [22, 23].

**Entecavir**

Entecavir is a nucleoside analogue which inhibits viral polymerase activity and both minus and plus strand DNA synthesis. It has potent anti-viral activity and leads to a profound decrease in viral load in both HbeAg-positive and negative patients [24, 25]. The incidence of entecavir resistance also remains low in naïve patients even after four years of treatment but despite these encouraging findings, HbeAg seroconversion remains low and comparable to that observed with other nucleoside analogues [26, 27]. However, when entecavir is administered to patients with lamivudine resistance, entecavir-resistant mutations develop in at least 35% of patients after four years [28]. Current data suggests that entecavir resistance follows a ‘two-hit’ model with primary resistance occurring at position rt 204 followed by secondary mutations at positions rt184, rt 202 or rt 250 leading to higher entecavir resistance [29]. Although lamivudine-resistant strains exhibit intermediate sensitivity to entecavir, this only occurs when entecavir is administered at a higher dose of one milligram per day. Once secondary mutations develop, entecavir resistance occurs followed by viral breakthrough and the only other options for treatment are to add adefovir or tenofovir. This suggests that entecavir should not be administered to lamivudine-resistant patients but may be a better option for nucleoside-naive patients.
Tenofovir

Tenofovir is a purine nucleotide analog and exhibits potent inhibitory activity against a wild type and drug-resistant mutants such as lamivudine and entecavir resistant strains. Tenofovir has been used mainly in HIV-HBV coinfection patients as tenofovir is also active against HIV reverse transcriptase. Although experience with tenofovir is limited in patients with chronic HBV, two recent studies comparing tenofovir 300mg per day versus adefovir 10 mg per day eAg-negative and -positive patients, respectively, were recently published [30]. The authors reported that viral suppression occurred in more HbeAg -negative patients receiving tenofovir than adefovir (93% versus 63%, p < 0.001). No mutations of HBV DNA polymerase associated with tenofovir resistance were noted and the HBV DNA response to tenofovir was similar in patients regardless of whether they had been exposed to lamivudine. However, the rate of HbeAg seroconversion was comparable to other nucleoside analogues. Due to its spectrum of activity, tenofovir appears to have a role in both naïve patients and in those with first-line treatment failure particularly as in vivo evidence suggests it is active against lamivudine, entecavir, adefovir and telbivudine resistant mutants.

Telbivudine

Telbivudine is a nucleoside analogue with strong antiviral effects comparable to entecavir in clinical trials on HBeAg-positive and negative patients [31, 32]. Although the rate of HbeAg seroconversion is comparable to lamivudine and entecavir, telbivudine administration is associated with a resistance rate of approximately 10% per year. Telbivudine selects for the rt M204I mutation which also confers resistance to lamivudine and entecavir but is sensitive to adefovir and tenofovir. Although telbivudine can be used for nucleoside naïve patients and patients with adefovir resistant strains, the lower rates of viral resistance observed with entecavir and tenofovir will probably lead to restricted use of telbivudine. Although it remains to be seen whether a combination of anti-virals or the sequential addition of these medications would be best for suppressing viral load and clinical status prior to LT, clinicians need to be cognizant that most deaths in these patients occur within the first six months of treatment, reflecting the severity of their underlying liver disease [15].

USE OF HEPATITIS B POSITIVE DONORS

Due to the persistent shortage of donors for LT, the use of HBV-positive donors has been utilized in selected recipients since the mid-1990’s. A number of studies have reported that core antibody donors should not be used in naïve recipients due to an extremely high risk of transmitting HBV to the recipients, regardless of the donor’s surface antibody status [33]. Core antibody donors may be used safely in surface antibody recipients as the risk of HBV transmission is negligible but when used in core antibody recipients who are surface antibody negative, the risk of acquiring HBV is at least 13% (Table 1). However, a recent case series reported that one out of four recipients who were core and surface antibody positive became HBSAg positive four years after each had received a core antibody positive living graft and lamivudine prophylaxis [34]. Further investigations in this patient demonstrated the HBsAb titer was less than 10 IU/L whereas the other patients had titers greater than this. Patients who receive hepatitis B donors and are at high risk of acquiring HBV should be treated with anti-virals and HBIG although the combination and duration of therapy varies between transplant centers [35, 36]. Recently, a study based on 89 liver transplant programs worldwide reported that all programs used nucleos(t)ide therapy in core antibody recipients of core antibody donors [37]. However, lamivudine was used the greatest (58% for US physicians and 81% for non-US physicians) and HBIG was used most frequently in the US (69% versus 46%, P = 0.03). Although 81% of physicians used nucleos(t)ide therapy indefinitely, the duration and method of administration of HBIG varied widely.

PREVENTION AND TREATMENT OF RECURRENT HEPATITIS B AFTER LIVER TRANSPLANTATION

The initial results of LT for HBV were very poor due to universal recurrence of HBV leading to early graft loss and very poor patient survival [38-40]. However, the introduction of intravenous HBIG in the early 1990’s was a breakthrough in the management of these patients for although graft infection was not always prevented, at least it was delayed which led to improved patient and graft survival [41, 42]. With experience, it became evident that a variety of factors influenced the recurrence rate of HBV such as pre-LT HBV DNA viral load, duration of HBIG therapy and trough surface antibody levels. For example, HBV recurrence rates were very low in patients transplanted with ALF or hepatitis delta co-infection as HBV DNA levels are usually undetectable or very low, respectively in these conditions. (However, many patients with low or undetectable viral loads from these early studies would have positive levels now due to the development of more sensitive quantitative assays).

The use of lamivudine monotherapy to prevent recurrence also showed promise at one year with reinfection rates as low as 10% but at three years, HBV recurred in nearly 50% of patients [43]. This was not a surprising figure as high resistance rates are commonly observed in non-transplant patients and, as observed in patients receiving HBIG monotherapy, the risk of recurrence was greatest in patients with high HBV DNA levels at the time of LT. As HBIG and lamivudine work by different mechanisms, the combination of these two agents has been used as the standard of care for the prevention of HBV recurrence post-LT with recurrence rates ranging between 0-11% [44, 45]. However, treatment has not been standardized, particularly with the use of HBIG with some centers aiming for titers greater than 100 IU/L for the first six months while others aim for higher levels or use either fixed or variable dosing [46-50]. Regardless of the dose or frequency of intravenous HBIG therapy, all these combinations are highly effective regardless of pre-transplant viral load (Tables 2, 3).

There remain several concerns with the use of long-term lamivudine and intravenous HBIG for liver transplant recipients with HBV. As previously reported, the risk of lamivudine resistance increases with the duration of treatment which can not only precipitate progressive liver injury and graft loss but several studies have also reported and increased rate of HBV recurrence in patients with lamivudine resistance at the time of LT [46]. Intravenous HBIG remains a prohibitively expensive medication with

The development of new potent oral nucleosid(t)es for HBV has not only expanded the therapeutic armamentarium for HBV treatment but also provided an opportunity to greatly modify our strategies for preventing and treating HBV recurrence [63]. As these drugs appear to have altered the natural history of HBV by leading to clinical stabilization and even reversal of decompensated cirrhosis, the number of patients transplanted for HBV-related liver failure is falling as they are more likely to be transplanted for HCC.

Clinical experience in the post-LT setting has been greatest with adefovir and entecavir which are gradually replacing lamivudine - studies on the other new agents are currently in progress. In transplant patients, entecavir appears to be more potent than adefovir with based on intermediate-term studies in the non-transplant population that have reported entecavir resistance in only 1% of patients after three to four years of continuous treatment [64, 65]. In contrast, several studies have reported considerably higher rates of adefovir resistance with nonresponse rates of at least 25% to the standard dose of 10 mg per day [66]. However, drug resistance and non-response to adefovir is extremely uncommon when adefovir is combined with lamivudine although cost-effectiveness studies comparing this combination with newer nucleosides/nucleotides have yet to be conducted. Although Schiff et al. also reported that adefovir monotherapy was effective in preventing HBV recurrence in the presence of lamivudine resistance post-LT, the investigators did not report the percentage of patients who received lamivudine/adeovir therapy versus adefovir monotherapy [19]. Due to entecavir's modest activity and high rates of viral resistance in the presence of lamivudine resistance in non-transplant patients, entecavir is usually not recommended for use in lamivudine-resistant liver transplant recipients with HBV.

Studies evaluating nucleosid(t)e therapy without HBIG may also be valuable in countries where HBIG is unavailable due to financial constraints. Recently, a seven year follow up study was reported by investigators from Hong Kong on 24 patients treated with lamivudine prophylaxis until drug resistance developed in seven patients leading to the addition of adefovir [67]. Although HBV DNA levels were too low for sequencing in three patients, four patients had the rtM204I mutation characteristic of lamivudine resistance. After a mean follow up of 150 weeks, HBV DNA was undetectable in 29% of patients, between 10-100 copies/ml in another 29% and between 10,000-100,000 copies/ml in 43% of patients. No resistance to adefovir was noted suggesting that lamivudine as monophylaxis followed by adefovir salvage clearly has an important role in post-LT HBV prophylaxis.

OUTCOMES OF LIVER TRANSPLANTATION FOR HBV

A retrospective review of the UNOS database between 1993 and 2004 reported that of 53,312 LT's performed in the United States, 2314 (4.34%) were for HBV [68]. Patients co-infected with hepatitis C were excluded from the analysis. 1816 cases (78%) were due to chronic HBV infection and 498 cases (22%) were due to HBV-related ALF. Interestingly, the investigators reported that three and five year survival rates for patients transplanted for chronic HBV
were better compared to patients transplanted for ALF from HBV or other liver transplant recipients. However, there were important imitations of this study. For example, only data from five states was analyzed as they historically received large numbers of immigrants from HBV endemic areas. In addition, the authors also did not report the percentage of patients transplanted for HCC related to underlying HBV nor the impact of post-transplant HBV treatment on outcomes. An additional retrospective study of 104 patients from Europe reported 5 year patient and graft survival rates of 80% and 73%, respectively [69]. In multivariate analysis, factors associated with poor patient survival were advanced recipient age, high body mass index, cyclosporine-based immuno-suppression and increased cold ischemia time. Risk factors for graft cirrhosis included viremia greater than 10 copies/ml, nucleos(t)ide prophylaxis without HBIG, mycophenolate mofetil use for less than one year and biliary tract complications.

To address the impact of HBIG and oral anti-virals on outcomes of post-transplant HBV, investigators from the Mayo clinic analyzed survival of LT recipients with HBV in the United States over the last 15 years to examine the effect of these innovations [70]. This retrospective analysis was conducted based on data collected prospectively by UNOS in all adult (older than 18) patients undergoing primary LT in the United States between 1987 and 2002. Patients were divided into three groups: era 1 (1987-1991), era 2 (1992-1996), and era 3 (1997-2002). Era 1 consisted of 6,708 patients (675 with HBV), era 2 consisted of 13,995 patients (1,005 with HBV), and era 3 consisted of 20,730 patients (1,723 with HBV). An important observation of patients from era 3 was that they were older and had less advanced liver disease and shorter ischemic time during LT. The

---

**Fig. (1).** Suggested algorithm for flowchart for HBV prophylaxis using HBIG and nucleosides/nucleotides.
survival of patients with HBV was significantly better for era 2 than for era 1 ($P < 0.01$) and for era 3 than for Era 2 ($P < 0.01$). Unlike previous reports, fulminant disease and Asian race had no effect on patient survival. The authors concluded that the data underscored the effectiveness of therapeutic innovations over the past two decades and reflected the timely and widespread adoption of these measures by transplant centers nationally.

SUMMARY

Transplant physicians will need to be well-versed with the new generation of anti-HBV medications, particularly as HBIG may play a lesser role and be confined only to the early post-LT period. Anti-viral monotherapy with vigilant monitoring for drug resistance appears to be the most-cost-effective approach to the management of these patients, particularly in health care systems which do not use HBIG due to its prohibitive cost, and hopefully data from well-designed randomized studies will guide transplant physicians in the care of these patients [71]. Until the results of these studies are available, one reasonable strategy is to treat wait-listed patients with oral anti-virals in an attempt to render them HBV DNA. At the time of LT, HBV DNA levels should be repeated in order to stratify them into a low versus high recurrence group (Fig. 1). HBIG should be initiated at LT and continued with oral antivirals for at least twelve months at which point HBIG may be discontinued in low risk groups while oral agents indefinitely continued in parallel with frequent monitoring of liver function tests, HBV DNA and HBV markers. Patients at high risk of recurrence should be maintained on HBIG and oral agents indefinitely together with frequent monitoring of liver function tests, HBV DNA and HBV markers. However, this recommendation will undoubtedly evolve as it is likely the newer generation of more potent oral anti-virals may minimize or even obviate the need for HBIG in carefully selected patients [72]. However, unless restricted by limited health care resources, transplant physicians should strive to practice evidence-based medicine and resist the temptation to use these medications ad hoc until data from prospective randomized studies and the appropriate economic analyses confirm these hypotheses.
